Abstract

The purpose of this study was to test the hypothesis of whether the center of rotation (COR) in the transverse plane of the knee is in the medial side during normal walking in a manner similar to that previously described during non-ambulatory activities. The kinematics for normal knees was obtained from 46 knees during normal walking using the point cluster technique. The COR of the medial–lateral axis of the femur relative to the tibia was determined during the stance phase of walking. The hypothesis that the COR is in the medial side during stance was not supported by this study. The average COR during the stance phase of walking was in the lateral compartment for all 46 knees. In addition, the instantaneous COR occurred on the medial side on average <25% of the time during the stance phase. Thus, while the COR is predominantly on the lateral side of the knee during walking, the normal function of the knee during walking is associated with both lateral and medial pivoting. These results also demonstrate the importance of describing knee kinematics in the context of a specific activity or the constraints of the test conditions.

Keywords: Knee kinematics; Center of rotation; Lateral pivoting; Medial pivoting; Natural knee movement; Knee prosthesis

1. Introduction

The normal function of the knee requires a subtle balance between stability and mobility that depends on the interaction between the ligaments, joint surfaces and muscles spanning the joint. While the joint provides a high degree of mobility for large flexion motion, there is a range of laxity (Markolf et al., 1976) in other degrees of freedom that is required for normal function during certain activities. For example, there is a unique combination of flexion, anterior–posterior (AP) translation and internal–external (IE) rotation that occur during walking (Dyrby and Andriacchi, 2004) that is different from what would occur during deep squatting or a passive flexion/extension motion. The direction and phasing of these relationships between the primary (flexion) and secondary movements (AP and IE) will determine the location of the center of rotation (COR) of the knee in the transverse plane (Banks and Hodge, 2004).

The location of the transverse plane COR represents the motion of the medial and lateral condyles of the femur relative to the proximal tibia during a specific activity and is an important factor in attempting to restore normal function after reconstructive surgery such as total knee replacement (TKR) and anterior cruciate ligament (ACL) reconstruction.

Asymmetry in the motions in the medial and lateral compartments depends on the internal–external rotation and can be influenced by internal structures in the joint. For example, the anatomy of the knee suggests that the medial compartment has a more conforming contact than the lateral compartment (Kapandji, 1987). In addition, the lateral meniscus is more mobile than the medial meniscus (Kapandji, 1987; McMahon and Kaplan, 2006) suggesting that the COR of the knee is in the medial compartment. In addition, an in vivo study of knee kinematics during deep...
knee bending and chair rising (Komistek et al., 2003) as well as in vitro studies of flexion/extension motion (Blaha et al., 2003; Freeman and Pinskerova, 2005; Iwaki et al., 2000) reported that the tibiofemoral contact points had larger AP movement in the lateral than medial compartments. While the above studies of non-ambulatory activities suggest that the knee predominately translates on the lateral side and thus the COR is in the medial side of the knee, it remains to be seen whether these observations can be extrapolated to walking. In fact, studies of ambulatory activities (Andriacchi et al., 2003; Dyrby and Andriacchi, 2004; Lafortune et al., 1992) demonstrate that knee kinematics are uniquely dependent on the specific activity and suggest that the AP motion of the knee is not predominantly in the lateral compartment during ambulation.

Given that walking is the most frequent activity of daily living and understanding the relative movement between the femur and tibia during walking can influence the success or failure of various reconstructive procedures of the knee, it is important to quantitatively assess the location of the COR, which represents the relative movement between the femur and tibia in the medial and lateral compartments during walking.

The purpose of this study was to test the hypothesis that the transverse plane COR is in the medial side of the knee, which represents greater tibiofemoral AP movement in the lateral than medial compartments during normal walking as suggested in previous studies of non-ambulatory activities.

2. Methods

This study measured knee kinematics during walking to determine the movement of the axes of the femur with respect to the tibia. The average location of the transverse plane COR was determined during stance phase, from heel strike to toe off, using a previously described method (Banks and Hodge, 2004). The percentage of time that the instantaneous COR was medial to the center of the tibia or lateral to the center of the tibia was tested to determine the frequency of time the knee pivoted medially or laterally during the stance phase of walking.

Twenty-three healthy subjects (14 males and 9 females, age 37 ± 12 (s.d.) years, body mass index 23.6 ± 2.4 (s.d.) kg/m²) without knee pain or injury histories were recruited for the study. The study was approved by the IRB and an informed consent was obtained from each subject before the test.

The subjects were tested bilaterally at a self-selected normal walking speed and six degrees of freedom knee joint kinematics were measured using the point cluster technique (PCT) (Andriacchi et al., 1998). With the PCT, clusters of nine and seven reflective markers were distributed on the thigh and shank, respectively, to predict the motions of the underlying femur and tibia (Fig. 1). Cluster coordinate systems were calculated for the femur and tibia through the markers on bony landmarks (markers with x marks; red, online) on the femur and tibia.

Fig. 1. Point cluster technique is used to measure the kinematics of the femur and tibia. Clouds of skin markers (blue, online) were used to track the motions of the thigh and shank which were translated as the motion of femur and tibia through the markers on bony landmarks (markers with x marks; red, online) on the femur and tibia.

The average COR of the medial–lateral axis of the femur (Fig. 2) was calculated from the lines in a least square sense.

normal walking, locations of the marker clusters were tracked in three-dimensional space and the cluster coordinate systems of thigh and shank were calculated. Using the information about the relative locations of the anatomic coordinate systems to cluster coordinate systems obtained in the static reference trial, the locations of the femur and tibia were calculated.

An equation for the line representing the medial–lateral axis of the femur projected on to the transverse plane of the tibial coordinate system was calculated from the lines in a least square sense.

\[ a_{x}x + b_{y}y = c, \]  

where \( x \) and \( y \) represent the medial–lateral and AP directions, respectively, as shown in Fig. 2.

The average COR of the medial–lateral axis of the femur (Fig. 2) was calculated by solving the least-squares system of equations of the lines (Banks and Hodge, 2004) defining the medial–lateral axis projected on the transverse plane of the tibial axis during the stance phase of walking.

\[
\begin{bmatrix}
    a_{1} & b_{1} \\
    a_{2} & b_{2} \\
    \vdots & \vdots \\
    a_{n} & b_{n}
\end{bmatrix}
\begin{bmatrix}
    x \\
    y
\end{bmatrix}
=
\begin{bmatrix}
    c_{1} \\
    c_{2} \\
    \vdots \\
    c_{n}
\end{bmatrix}.
\]  

(2)
The system of Eq. (2) describes the medial–lateral axes for time $i = 1$ through $n$ samples. Thus, the average COR ($x_c$, $y_c$) for the entire stance phase ($n$ samples) is

$$
\begin{bmatrix}
    x_c \\
    y_c
\end{bmatrix}
= 
\begin{bmatrix}
    \begin{bmatrix}
        a_1 & b_1 \\
        a_2 & b_2 \\
        \vdots & \vdots \\
        a_n & b_n
    \end{bmatrix} & \begin{bmatrix}
        a_1 & b_1 \\
        a_2 & b_2 \\
        \vdots & \vdots \\
        a_n & b_n
    \end{bmatrix}
\end{bmatrix}^{-1}
\begin{bmatrix}
    c_1 \\
    c_2 \\
    \vdots \\
    c_n
\end{bmatrix}
$$

The instantaneous CORs between two consecutive time frames were calculated as shown above and the percentage of time (frequencies) when the COR was medial to the center of the tibia during the stance phase of walking was obtained.

For statistical analysis, a one-sample $Z$-test was used considering the correlation between the measurements from left and right knees of each subject in calculating variance. The $x_c$ value of the average COR Eq. (3) was tested to determine if it was medial or lateral to the center of the tibia. We also tested whether the COR was in the medial side for more than 50% of the time during the stance phase of walking.

Since skin movement can affect the calculation of the average COR from PCT, its robustness was tested by adding Gaussian random noise in the AP translation and IE rotation for each frame. This process was repeated 1000 times to calculate the empirical 95% confidence interval of the average COR for each gait trial. During this process, the standard deviation of the Gaussian random noise was set to 1, 2 and 3 mm for AP translation and 1°, 2° and 3° for IE rotation to calculate the robustness at different levels of noise.

3. Results

The hypothesis that the transverse plane COR of the knee is in the medial side during stance was not supported by this study. The average COR calculated during the stance phase of normal walking was in the lateral compartment for all 46 knees ($p<0.01$) (Fig. 3). The average ($9.0 \pm 3.7$ (s.d.) cm) and median (8.7 cm) locations of the average COR were lateral (extraarticular) to the center of the tibial surface. The subjects walked at an average speed of $1.41 \pm 0.18$ (s.d.) m/s.

In addition, both the average ($24.9 \pm 11.6$ (s.d.)%) and median (20.5%) percentage of time when the instantaneous COR was in the medial side during stancce were significantly ($p<0.01$) <50% indicating that the knee spent a significantly greater amount of time pivoting laterally during walking. The average time when the instantaneous COR was in the medial side was <50% during the stance phase of walking for 44 knees out of the 46 knees (Fig. 4), suggesting that the instantaneous COR was predominantly lateral to the center of the tibia during the stance phase of walking.

When all the instantaneous CORs during stance phase for each subject’s gait trial were pooled, the median of the total instantaneous CORs was 6.2 cm lateral to the center of the tibia and 74.8% of the instantaneous CORs were in the lateral side of the knee.

The robustness of the calculation of the average COR was tested for nine different levels of Gaussian random noise in the AP translation and IE rotation as shown in Table 1. Even when the standard deviations were 3 mm and 3° for the Gaussian noise for AP translation and IE rotation, respectively, the average COR was significantly in the lateral side for 40 knees (87%). None of the knees had an average COR significantly in the medial side for any level of noise.

4. Discussion

The results of this study did not support the hypothesis that the transverse plane COR of the knee was predominately on the medial side during walking. Rather, the average COR was in the lateral (extraarticular) side of the knee. While the instantaneous COR does move to the medial side during a portion of stance the vast majority...
spent, on average, more than 70% of time with a COR in the lateral side.

These results are consistent with previous kinematic studies of walking (Andriacchi et al., 2004; Lafortune et al., 1992) that report AP and IE motions. These studies show that at heel strike the femur is rotated internally and translated posteriorly relative to the tibia (Fig. 6(a) and (b)). Throughout the stance phase of walking, the femur rotates externally and translates anteriorly relative to the tibia. The combination of the translation and rotation during the stance phase of normal walking suggests that the COR of the knee is on the lateral side for most of the time during the stance phase of normal walking.

Studies of patients with ACL-deficient knees (Andriacchi and Dyrby, 2005) showed a pattern of AP and IE motions that are consistent with the patterns found in healthy knees in this study suggesting that the COR of the knee is predominantly in the lateral side in both healthy and ACL-deficient knees. These results are consistent with studies of patients with certain types of TKR (Banks and Hodge, 2004) that show the average COR is in the lateral side of the knee.

While the majority of the instantaneous CORs were distributed close to the center or just lateral of the center of the tibia (Fig. 5), there were extreme values on both the medial and lateral sides. An extreme COR value indicates that there is almost pure AP translation occurring during this instant in the stance phase of normal walking.

The PCT uses skin markers to predict the motion of the underlying bones, so the accuracy in detecting bone motions can be affected by skin movement (Alexander and Andriacchi, 2001). Thus, the robustness of the calculation of the average COR was tested by adding Gaussian random noise in measuring AP translation and IE rotation. Even after considering the uncertainties in the measurements, the majority of knees (87%) had lateral pivoting patterns.

A simple flexion/extension motion of cadaver knees showed that the lateral compartment has a larger AP range of movement than the medial compartment (Blaha et al., 2003; Freeman and Pinskerova, 2005; Iwaki et al., 2000) suggesting that the COR of the knee is in the medial compartment during passive knee motions. The COR of the knee also has been shown to exist in the medial compartment during in vivo open-chain activities, but it has not been shown during normal walking. Based on the studies of non-ambulatory activities it has also been suggested that designs of TKR should incorporate articular
surface shapes that guide medial pivot movement (Blaha, 2004; Schmidt et al., 2003). Though a previous study reported that the COR of the knee is in the medial compartment during walking for healthy subjects (Komistek et al., 2003), the tests were conducted at an unrealistically slow speed; 0.28–0.56 m/s while normal speed is ~1.24 m/s in healthy subjects (Mundermann et al., 2004).

The results of this study indicate that knee kinematics during walking are different from kinematics measured during non-ambulatory activities (Blaha et al., 2003; Dennis et al., 2005; Freeman and Pinskerova, 2005; Iwaki et al., 2000; Komistek et al., 2003; Li et al., 2006; Mahfouz et al., 2004) or observations of passive knee anatomy (Kapandji, 1987) that report that the COR of the knee is in the medial compartment. Taken together with the findings of other studies the results support the conclusions that knee joint kinematics are highly dependent on the specific activity (Andriacchi et al., 2004; Dyrby and Andriacchi, 2004) and knee kinematics should be described in the context of the activity.

While the COR is predominantly on the lateral side of the knee during walking, the instantaneous COR does occur on the medial side about 25% of the stance. Thus, the normal knee function is associated with pivoting in both the medial and lateral sides of the knee. The results of this study indicate that TKR designs should permit lateral pivoting motions during normal walking (the most frequent activity of daily living) while permitting the capacity for medial pivoting motions during non-ambulatory activities such as squatting. The results also suggest the importance of describing knee kinematics in the context of a specific activity or the constraints of the test conditions. Thus, it is not possible to extrapolate knee kinematics from non-ambulatory activities to ambulatory kinematics.
